

Published vs Data-Mined (OOS Only)

Figure 1: Published vs data-mined returns in calendar time (post-sample only). For each calendar month, we compute the equal-weighted cross-sectional average of scaled long-short returns across all published signals that are at least five years past their original-sample end date. Returns are scaled so that each signal's in-sample mean equals 100 bps per month. The data-mined line averages matched Compustat accounting strategies with $|t| > 2.0$ in the original sample period, where matches are constructed separately for each published signal. The plot shows a trailing 60-month (5-year) rolling mean. Only post-sample observations are included, removing in-sample returns which are mechanically high due to signal selection. Following Campbell (2024), signals with fewer than 5 years of post-sample data are excluded, and signals in decade cohorts with fewer than 10 members are dropped.

Published Returns by Cohort (OOS Only)

Figure 2: Published signal returns by sample-end decade cohort (post-sample only). Signals are grouped by the decade in which their original sample ended (e.g., “1990s” includes signals with sample end dates between 1990 and 1999). For each cohort and calendar month, we compute the cross-sectional average of scaled long-short returns across signals in that cohort that are at least five years past their original-sample end date. Returns are scaled so that each signal’s in-sample mean equals 100 bps per month. Faded colored lines show the trailing 5-year mean return for each cohort; the bold black line shows the equal-weighted average across all signals. Only post-sample observations are included. Each cohort’s line begins when its earliest signal enters the out-of-sample period. Persistent level differences between cohorts would indicate cohort effects; synchronized movements at the same calendar dates indicate time effects. Following Campbell (2024), signals with fewer than 5 years of post-sample data are excluded, and cohorts with fewer than 10 signals are dropped.

Data-Mined Returns by Cohort (OOS Only)

Figure 3: Data-mined signal returns by sample-end decade cohort (post-sample only). Signals are grouped by the decade in which their original sample ended. For each cohort and calendar month, we compute the cross-sectional average of scaled returns from the matched data-mined Compustat accounting strategies with $|t| > 2.0$ in the original sample period, using only observations past each signal's original-sample end date. Matches are constructed separately for each published signal. Returns are scaled so that each signal's in-sample mean equals 100 bps per month. Faded colored lines show the trailing 5-year mean return for each cohort; the bold black line shows the equal-weighted average across all signals. Only post-sample observations are included. Following Campbell (2024), signals with fewer than 5 years of post-sample data are excluded, and cohorts with fewer than 10 signals are dropped.

Risk: Published vs Data-Mined (OOS)

Figure 4: Risk-motivated signals: published vs data-mined returns in calendar time (post-sample only). For each calendar month, we compute the equal-weighted cross-sectional average of scaled long-short returns across published signals classified as “risk” that are at least five years past their original-sample end date. Returns are scaled so that each signal’s in-sample mean equals 100 bps per month. The data-mined line averages matched Compustat accounting strategies with $|t| > 2.0$ in the original sample period, where matches are constructed separately for each published signal. The plot shows a trailing 60-month (5-year) rolling mean. Following Campbell (2024), signals with fewer than 5 years of post-sample data are excluded, and signals in decade cohorts with fewer than 10 members are dropped.

Mispricing: Published vs Data-Mined (OOS)

Figure 5: Mispricing-motivated signals: published vs data-mined returns in calendar time (post-sample only). For each calendar month, we compute the equal-weighted cross-sectional average of scaled long-short returns across published signals classified as “mispricing” that are at least five years past their original-sample end date. Returns are scaled so that each signal’s in-sample mean equals 100 bps per month. The data-mined line averages matched Compustat accounting strategies with $|t| > 2.0$ in the original sample period, where matches are constructed separately for each published signal. The plot shows a trailing 60-month (5-year) rolling mean. Following Campbell (2024), signals with fewer than 5 years of post-sample data are excluded, and signals in decade cohorts with fewer than 10 members are dropped.

Agnostic: Published vs Data-Mined (OOS)

Figure 6: Agnostic signals: published vs data-mined returns in calendar time (post-sample only). For each calendar month, we compute the equal-weighted cross-sectional average of scaled long-short returns across published signals with no specific theoretical motivation (“agnostic”) that are at least five years past their original-sample end date. Returns are scaled so that each signal’s in-sample mean equals 100 bps per month. The data-mined line averages matched Compustat accounting strategies with $|t| > 2.0$ in the original sample period, where matches are constructed separately for each published signal. The plot shows a trailing 60-month (5-year) rolling mean. Following Campbell (2024), signals with fewer than 5 years of post-sample data are excluded, and signals in decade cohorts with fewer than 10 members are dropped.
